Report
of

Fire Endurance Tests of Prefabricated Exterior Wall Panels

Test Report No. TC10219-b3: 573266

ADDENDUM

Two fire tests of prefabricated exterior walls were made at the National Bureau of Standards and two at a laboratory in the Netherlands to provide data for comparisons of the four constructions. Certain deviations in the Standard Test Methods, made necessary by the design of the Netherlands test furnace, were carried through all the tests. The tests do not provide the basis for standard fire ratings because of these deviations but show the relative performances of the four constructions under essentially equal test conditions.

1. INTRODUCTION

In compliance with a request of May 25, 1954 (file 10077) from the Corps of Engineers, Northeast District, two fire endurance tests of prefabricated panels for exterior walls were performed and two other fire tests of different panels for the same purpose were witnessed. The latter tests were conducted at the T. V. O. I. Fire Research Laboratory, Delft, Holland.

The tests were made to provide data for comparisons among the four constructions tested, both as to fire resistance and as to the extent of repairs which would be necessary to make the assemblies fit for reuse.

TESTS ON INSULATED WALLS

2. TEST DETAILS

The four constructions tested, in order, were:

Test 1. A hollow wall with an air space of about 2 in. (5 cm) between the inner and outer faces. The outer face consisted of precast high density concrete channel slabs with transverse ribs. Each slab was 10 ft. 6 in. (318 cm) high, 2 ft. 6 in. (75 cm) wide, about 2 in. (5 cm) thick through the web and about 5.5 in. (15 cm) thick through the channel flanges and transverse ribs. The exterior sides of the flanges were forced to fit the flanges of the adjoining slabs in a tongue-and-groove system. The slabs were cast in forms on a shock table and shocked repeatedly to obtain the high density. The inner face consisted of a pressed board of wood shavings bonded with portland cement which was coated on both sides with about 3/4 in. of a portland cement and sand mixture, giving an overall thickness of about 4 in. The total thickness of the test specimen was about 12 in. The details are shown in figure 1.

Test 2. A sandwich wall with 2 in. of mineral wool insulation between the inner and outer faces. The outer face was of the same type materials and design as that in test 1. The inner face consisted of precast concrete slabs 4 in. thick. The details are shown in figure 2.

Test 3. A wall consisting of three prefabricated panels, each of which was 9 ft. 11 3/4 in. high, 2 ft. 6 in. wide, and 4 3/4 in. thick, overall. Each panel consisted of a rectangular wooden frame to one face of which had been attached a sheet of 16 gage steel plate which projected on both sides of the frame and was bent to form interlocking joints with neighboring panels. The interior of the 3 in. deep wood frame had been filled with 9 lb/ft³ density mineral wool after which a corrugated sheet of 22 gage steel, coated with zinc, asbestos felt and a heavy asphaltic solution and aluminum painted on the outer side, had been attached to the other face of the frame. The mineral wool did not fill the 1 3/4 in. deep corrugations. The joints between panels in the interior or flat steel face were caulked and those in the exterior or corrugated face were stuffed with mineral wool and covered with full height 4 in. wide strips of the corrugated facing during erection. The details are shown in figure 3.

FDL219-63-PR3282

Test 4. A wall consisting of four prefabricated panels, each of which was 10 ft. high, 4 ft. wide, and 4 in. thick. Each panel consisted of a wood frame 9 ft. by 3 1/4 in. high by 1 ft. 11 1/2 in. wide by 3 1/2 in. thick which had been faced on the interior side with 1 in. plywood also with zinc coated steel and on the exterior side with .1 in. plywood clad with aluminum. The facings had been backed with asbestos paper and the space between facings filled with glass fiber insulation. The interior face projected 3 1/4 in. above the wood frame and the exterior face 3 1/2 in. below, each backed with 3/4 in. additional plywood. These projections, 11 1/2 in., provided holes and sockets for lag screws by which the panels were secured to 3 by 3 5/8 in. transverse sills at top and bottom during erection. All the surfaces of the wood components had been coated with a fire retardant paint except the metal clad faces of the plywood. The panels were tied together at erection by the sills and by 3/4 in. pipes which went through all four panels parallel to the faces near the top and bottom. The details are shown in figure 4.

3. TEST METHODS AND EQUIPMENT

It had been requested that the tests be performed to provide data for comparison of the various constructions. Therefore, the test conditions and methods were kept as nearly identical as practicable for each test. Whenever possible, the standard methods of fire tests of building Construction and Materials, ASTM E119-53 were followed. The furnace fires were controlled to produce temperatures close to those specified in E119-53, which include: 1500° F (830° C) at 5 min., 1300° F (704° C) at 10 min., 1500° F (843° C) at 30 min., 1700° F (927° C) at 1 hr., 1600° F (1610° C) at 2 hr., and 2000° F (1093° C) at 4 hr. The end point criteria followed were those applicable to non-bearing walls and partitions. They provide that the fire endurance limit shall be determined by one of the following:

1. The average temperature on the unexposed surface increases 250 degrees F above its initial value.
2. The temperature at any one point on the unexposed surface increases 320 degrees F above its initial value.

3. Flames or gases hot enough to ignite cotton-waste pass through the wall.

Certain deviations from the Standard Test Methods were necessitated by the test furnaces. Tests 1 and 2 were made in the wall test furnace of the T. U. O. Laboratories at Delft, Holland, shown in figure 5. This furnace was such that the specimen size was about 7 ft. 6 in. wide and 10 ft. 6 in. high. The furnace temperatures were measured by five chromel-alumel thermocouples symmetrically distributed throughout the furnace chamber. The junctions were bare and were located about 3 in. from the exposed surface. The unexposed surface temperatures were measured by five chromel-alumel thermocouples whose junctions were placed under 6 in. square felted asbestos pads, four of which were symmetrically distributed over the surface and the fifth placed over a joint between panels. Tests 3 and 4 were made in the wall test furnace of the National Bureau of Standards in Washington. The test frames ordinarily required a specimen 10 ft. high and 16 ft. wide but filler walls were built in to reduce the latter dimension to accommodate test specimens 8 ft. wide, thereby approximating closely the frame size of the Delft furnace. Therefore, the exposed areas of all four test specimens were approximately equal but were less than the minimum specified in the Standard Test Methods. Eleven chromel-alumel thermocouples were distributed symmetrically over the unexposed surface with their junctions under 6 in. square felted asbestos pads 0.4 in. thick. The numbers and placement of thermocouples on the unexposed surfaces of the four test specimens varied because of the available equipment and the number of panels and joints and other construction details, but were considered equivalent. No hose stream tests were made on any of the specimens.

4. RESULTS

4.1 Test 1

Test of precast shocked concrete outer face and cement coated fiber board inner face with 2 in. air space between. During the first 40 min., slight amounts of smoke and steam issued from joints; at 45 min., 2 explosions, cement coating of inner face fell off from core and covered observation ports; 50 min, another explosion; 53 min., fourth explosion; 2 hrs., fifth explosion; 2 hr. 10 min., hairline cracks in unexposed surface of center panel, upper section; 2 hr 20 min., gas off.

using a microscope. In fact all specimens were examined under a binocular microscope and the results of the examination were recorded. The following table gives the number of species found in each of the 100 samples taken.

DISCUSSION.

1. General Data.

The following table gives the number of species found in each of the 100 samples taken. The first column gives the number of species found in each sample, the second column gives the number of samples containing that number of species, and the third column gives the percentage of the total number of samples containing that number of species.

Immediately after the gas was turned off, the test specimen and frame were removed from the furnace. The insulation, inner face panel in the center and portions of those on either side had fallen into the furnace chamber. The only damage to the concrete outer face was a spalled spot about $\frac{1}{2}$ in. deep and 6 in. diameter in the center of the upper section of each panel. Collections of the outer face were negligible.

The control of the furnace temperature was such that the exposure severity was 67 percent of standard. The fire endurance limit was determined by temperature rise of 325 degrees at one thermocouple on the unexposed surface at 2 hr. 0 min. The thermocouple was on the face of the center panel. If the correction formula in M119 is applied to the temperatures indicated by the bare thermocouples, the correction is minus 3 min. Therefore, the corrected fire endurance is 2 hr. 3 min. The temperatures measured during the test are shown in figure 6.

4.2 Test 2

Test of precast and shocked concrete outer face, mineral wool insulation, and precast pumice inner face. Steam issued from the joints during the first 1 hr. 55 min. and slight amounts of smoke issued throughout the remainder of the test. Hairline cracks were observed in the unexposed surface at 45 min. and after about 3 hrs. the panels developed a warped appearance. The gas was turned off at 3 hr. 46 min.

Immediately after the gas was turned off, the frame and specimen were removed from the furnace. The center pumice panel and portions of those on either side had melted down; the mineral wool was in place except for the center section behind the area of melted pumice. The outer concrete face was unharmed and recovered from the deflections upon cooling.

The control of the furnace was such that the fire exposure severity was 96 percent of standard. The fire endurance limit was determined at 3 hr. 36 min. by temperature rise of 325 degrees at one thermocouple located on the unexposed face of the center panel in the upper half. If the correction formula in M119 is applied to the temperatures as indicated by the bare furnace thermocouples, the correction is minus 1 min. Therefore, a corrected fire endurance is 3 hr. 33 min. The temperatures measured during the test are shown in figure 6.

4.3 Test 3

Test of mineral wool filled metal faced prefabricated wall. At 5½ min., flames into furnace from one joint between panels, on exposed side; 6½ min., flames into furnace from other joint, exposed metal faces of all panels bowed toward flames; 10 min., yellow smoke from joints in unexposed surface; 13 min., flames into furnace from joints in exposed face almost out; 15 min., and after, repeated popping sounds; 31 min., flames out of furnace along top edge of specimen; 45 min., paint and/or bituminous coating on upper 1/3 of unexposed face blistered; 1 hr. 1 min., gas off.

Immediately after the gas was turned off, the test frame was removed from the furnace. The exposed face of the specimen was badly warped and a bright glow or flames in the interior were visible through the joints. The specimen was removed from the frame, the exposed faces removed from the panels and the fires in the interior extinguished with water. The insulation in the upper 3 to 4 ft. had slipped down, into the space resulting from the bowing or puffing out of the exposed face. The wood frame and insulation were badly charred.

The furnace control was such that the fire exposure severity was 98.8 percent of standard. The fire endurance was limited to 35 min by 325 degree F temperature rise at one thermocouple on the unexposed surface. This thermocouple was located on the cover strip of one of the joints between panels. The applicable correction was minus 1 min. making the corrected fire endurance 34 min. The temperatures measured during the test are shown in figure 7.

4.4 Test 4

Test of metal clad plywood faced wall filled with glass fiber insulation. During the first 2 min., repeated popping; 3 min., voluminous flames into furnace from joints in exposed face, metal face bulged toward flame, smoke from joints in unexposed face; 6 min., offset of 1 in. along joint in unexposed face as north panel bowed out; 21 min., bright glow or flames in interior of north panel visible through joint in exposed face; 27 min., joint in unexposed face between north and north-center panels open 4 in., 34 min., popping sound, rest of unexposed face warped; 48 min., glow visible from unexposed side in

3 月 1 日 晴天。早晨 6 点左右，我从宿舍出来，发现宿舍前的草地上长满了嫩绿的小草，它们在微风中摇曳着，显得非常生机勃勃。我忍不住蹲下来，仔细观察起这些小草来。

卷之三

故人不以爲子也。子之不孝，則無子矣。故曰：「子不孝，無子也。」

the following example. The author does not subject the reader to the usual
long and tedious varia. It is a simple
and lucid account of the history of
the language.

The placement of the furnace thermocouples for tests 1 and 2, at the Bell Laboratories, differed from the standard test and in that the thermocouples were set closer to the top and were about 3 in. from the exposed face rather than 6 in. The bare junctions would lead to higher temperature indications because the pipes and their thermal lag were eliminated. It would be experience has indicated exposure severities indicated by bare thermocouples differ by about 7 percent from those indicated by enclosed thermocouples in the same tests. The effect of the placement of the thermocouple junctions about 3 in. from the exposed surfaces should be small since the overall depth of the furnace chamber was only about 11 in. Temperature variations along the depth in such a furnace should be less than or, at worst, equal to those that might exist in a deeper furnace chamber.

These deviations from the Standard Test Method and the variations between the two test furnaces were such that, for the purpose of the comparisons for which the tests were conducted, their effects should be small. However, if fire resistance ratings should be desired for the various constructions tested, it would be necessary to perform further tests which would be in full compliance with the Standard Test Procedure.

5.2 Repairs Necessary for Tests

At or before the ends of the tests, one individual test specimen had been damaged to the extent that replacement or re-placement would be necessary. The condition and performance of the specimens during the tests would apparently require:

Test 1. The inner face would have to be replaced after a standard 2 hr. fire exposure or equivalent and the outer face panels should be patched but could be used as is.

Test 2. The inner face and the central panel insulation between the faces would have to be replaced and the outer wall panels would probably be damaged after a standard 3/4 hr. fire exposure, or its equivalent.

Test 3. The complete wall panels would have to be replaced after a 1/2 hr. standard fire exposure, or equivalent.

Test 4. The complete wall panels would have to be replaced after a 3/4 hr. standard fire exposure, or equivalent.
